Microcontroller Introduction

Microcontrollers can be found anywhere, from your cars stereo to missile launch panels and are usually cheap (around £2) and packed with information! They often come with crypto-engines (AES, DES and RSA are common) and hold all sorts of information like private crypto-keys for authentication or propietary algorithm implementations in the firmware or hardware, interesting all sorts of people into the contents of a microcontroller.

Packaging and De-packaging

Typically microcontrollers are too small and fragile to use as they are fabricated (with fabrication lengths shrank to micrometers) and so they are packaged[5]. Packacking material ranges depending on the microcontroller and its intended use, but is usually hard epoxy resin [4] [5]. The packaging tries to protect the microcontroller from its external environment (humidity, radiation, temperature, crashes etc.) and also from prying eyes. Military-grade chips come with a lot of additional circuitry on the packaging whose responsibility is to detect tampering and respond in a suitable manner (even self destruction!) [5].

De-packaging is not always requierd and the methods depend on the packaging used and protective mechanisms in place, but on epoxy-packaged chips one can etch the epoxy away by using HNO_3 or H_2SO_4 and then cleaning the chip in an ultrasonic bath [4] [5]. For other packaging types, e.g. metal, ceramic or plastic, one can use similar techniques and tools, e.g. drills or a blowtorch [5].De-packaging is usually easier than expected and removing simple epoxy resin can [illegible] with readily available chemicals [5]. Fig. [illegible] show a microcontroller in its factory resin p[illegible] exposed die after chemical decapsulation[6].

tampering detection means detecting abnormalities in voltage, clock frequency, radiation, tilting etc.

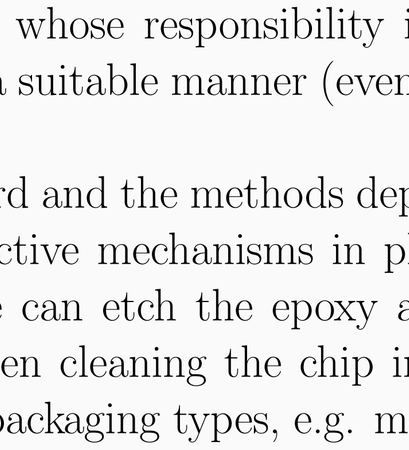

Fig. 2: The exposed die of an ATmega328.

Attack Types

Non-invasive attacks are cheap and easy to perform and require no decapsulation. Popular methods include are power analysis and fault injection, where faults may be injected by exposing the chip to environmental conditions that it was not meant to work in. **Non-Invasive** and **Semi-invasive** attacks are more technical, expensive and lengthier to perform as they require decapsulation and specialized machinery, but yield more information about a die. Attacks under these categories include micro-probing the device, inducing faults using lasers and physical modification of the chip using FIBs.

Sample Attack

A simple clock glitch attack could be performed against an ATmega644, in order to make it dump its memory, since it operates on an external clock signal and we know how many cycles each instruction takes. We would use an FPGA to deliver both the clock signal and the glitch itself [1] [3].

We first need to synchronize with some *trigger* event and [illegible]ycles from there in order to inject our glitch in the [illegible]ate cycle. Suppose there's a `while`-loop in the [illegible], and it looks similar to Table **??**
